Abstract: Young professionals and scientists are now attempting to limit the usage of synthetic fibres and petroleum-based polymers, as these materials are not biodegradable and are detrimental to the environment. Natural fibre products are in higher demand around the world since they are good in sustainability, availability, strength, durability appearance, and physically strong. Natural fibres are employed in green composites because they perform better than synthetic fibres. Injection moulding, compression moulding, thermoforming, and extrusion processes are used to create these products. This review article discusses the many types of manufacturing processes utilized in green composite, as well as the benefits, drawbacks, and challenges associated with employing green composite. **Keywords:** Green Composite, Natural Fibre, Thermoplastics Polymer and Thermosetting Polymer.

I. INTRODUCTION

Green composites are composites made of biopolymers or polymers reinforced with bio fibres, Or, to generate a herbal composite fabric, combine green composite plant fibres with natural resins[1]. Simply said, green composites are the fabric of the future for tolerable composites. These days, there's a lot of focus on green composite selection. They are the upcoming era of sustainable composite materials and the combination of natural fibres and herbal resin. So, inside the green composite, either natural assets or natural matrices (polymers) might be present, which would be from com composite. In the end, the goal is to create a strong composite, but they should not be as heavy as metals and should be light in nature. They also need to reduce density and weigh the benefits and drawbacks of green composites. They might be biodegradable and recyclable. Because you have recyclability. Because environmental issues are such a big deal these days, they're recyclable or biodegradable [2]. If you're working with biodegradable materials, you'll always have an advantage. As a result, it is up to novice composites to get it. It has to be made up of something grainy as a stupid term, and it no longer maintains its synthetic nature (necessarily inexperienced in colouration). It is not, however, synthetic in nature. It should have been derived from natural resources such as plants, animals, and birds. Then we declare it to be a green composite. As far as their textile nature is concerned, at least one component in the fibre or the resin, or both of these, must be green in nature [3].

II. NATURAL FIBRE

Herbal fibres are a type of fibre that comes from plants and animals. Cotton, silk, wool, jute, linen, and coir, for example. A composite is a material that is made up of at least two unusual materials. This description would include bricks, concrete, wood, bone, and synthetic composites, as well as fibre-bolstered polymers (FRP). Because of their great strength, stiffness, and combination of low weight, FRPs are being used to fabricate a variety of structures. They're usually made of epoxy resin and synthetic fibres. High-performance composite materials are the name given to these materials. Natural fibres (NFs) specifically as a reinforcement in composite materials are being considered a preferred solution for one-of-a kind programmes, particularly in light of sustainable materials. These NFs have a number of advantages, including the capacity to replace expensive artificial fibres. Bio-composites have also been created using these NFs. The evolution of composite materials is depicted.

Figure 1: classification of Natural Fiber [4].

III. CLASSIFICATION OF GREEN COMPOSITES

Green composites on sort of reinforcement and polymer materials are divided into 3 primary types as stated right here.

(a) Definitely, renewable composites, wherein both matrix and reinforcement are from renewable resources.

(b) Partly renewable composites in which matrix is obtained from renewable sources and bolstered with synthetic fabric.

(c) In part renewable composites in which artificial matrix is reinforced with natural biopolymers

IV. TYPES AND PROPERTIES OF GREEN COMPOSITES

A starch-based completely, dispersion-type biodegradable resin and cellulose fibres were used to create environmentally acceptable green composites. The mixture of dispersion-type biodegradable resin and cellulose fibres was thoroughly mixed with the help of a home-use mixer and a stirrer and then dried in the air or in a vacuum. Traditional hot urgent composites were structured at a constant temperature of 140 °C and pressures of 10 to 50 MPa, and their flexural electricity and flexural modulus extended as the moulding stress increased. The composites were made using a biodegradable polymer-based on starch and Manila hemp fibres. Inexperienced composites tensile energy is largely influenced by fibre composition. By employing weight, the tensile strength of go-ply composites would rise by nearly 50% with the fibre content material.

V. THERMOPLASTICS

Thermoplastic is a type of plastic polymer that softens as the temperature rises and hardens as the temperature falls. The majority of thermoplastics have a high molar mass. And their polymer is the result of adding intermolecular pressure to the collection of moles. And to become weaker as the temperature rises, increasing the softness of plastic. They may be turned into viscus (concentrate or viscous) liquid as a result of this. Which can be moulded into a variety of shapes and whose fibres may also be stretched. Nylon is a thermoplastic that is far too important. Thermoplastics are the finished products of the thermoforming process. The ability of thermoplastics to withstand repeated activation is

one of their key advantages. As a result, it may easily be reheated and moulded. This property also allows thermoplastics to be reused [5].

Advantages of Thermoplastics

- Rapid Processing
- Smooth Rework
- No chemical reaction takes place in the course of software processing
- No curing required
- Remodel able

Disadvantages of Thermoplastics

- Confined-carrier temperature performance
- It has the tendency to shape weaker adhesive bonds

VI. FABRICATION AND MATERIAL SELECTION

Fabrication technologies are a key predictor of material choice, with silicon still holding the top spot. Micro actuators may be able to be mass-produced at a reasonable cost due to their ease of fabrication and compatibility with current ICs. Nobody knows if there is a material that is suitable for all types of movements. Rapid-reaction materials, for example, may demand a high actuation voltage, whereas sluggish-response materials may require a low actuation voltage. If a fast response is desired in high-velocity packages or switches, substances such as diamond, silicon carbide, alumina, silicon nitride, and silicon are suitable options. Titanium carbide, tantalum carbide, or tungsten carbide can be utilized if a lot of force is required. However, using non-IC-preferred materials will increase production costs and complexity. As a result, while constructing a micro actuator, a trade-off is unavoidable. Many strategies exist, such as the Ashby method, which is a Multi-Goal Decision-Making strategy, and the technique for Order Preference by Similarity to Ideal Solution.

• Thermoforming

The process of heating a thermoplastic sheet to its softening factor is known as thermoforming. The sheet is stretched and controlled in a one-sided mould. After that, it cools to the appropriate shape. To get a sheet to agree to its final shape, the most popular procedures are vacuum forming, stress

forming, and mechanical forming. Thermoforming comes in a variety of forms and can be employed in a variety of sectors [6, 7].

Applications

The thermoforming process can also be used in a wide variety of applications. Some of the most common include,

- Retail clamshell packaging
- Packaging blisters
- Choose and location Tray
- Fabric and handling tray and covers
- Transport tray
- Clinical packaging
- Includes packaging

Drawback of Thermoforming

- The method is confined to skinny-walled designs
- Part thickness may be uneven in spots, inflicting vulnerable points
- It is slightly extra high priced than other plastic moulding techniques together with injection moulding
- It is able to require greater plastic than different strategies of plastic moulding
- It is not a flexible material process, as
- It is miles restrained to the plastic sheet

Compression Moulding

In comparison to injection moulding and transfer moulding, compression moulding is one of the most cost-effective moulding techniques [6]. It's a highly efficient and cost-effective method of creating composite components. It's a high-strain forming method in which molten plastic fabric is squeezed into a small empty space all at once, using heat and stress to conform to the shape of the mould. The material in thermoset compression moulding stays heated throughout the cycle, and a new rate of moulding powder can be fed in as soon as a moulded object is evacuated. However, unlike thermosets, thermoplastics must be chilled before hardening. As a result, before a moulded element can be removed, the entire mould must be cooled, and as a result, compression moulding with thermoplastics is rather slow. Compression moulding is most commonly used for thermosetting polymers such as phenolic, urea, melamine, and alkyd; however, it is not always employed for thermoplastics. However, when

extreme accuracy is required, thermoplastics are also compression moulded using an industrial machine, as seen in Figure 2

Figure 2: industrial unit compression moulding

Extrusion Moulding

Extrusion moulding is the process (shown in figure 3(a)) of shaping polymers or metals into certain shapes. Metal or plastic is melted and pressed through a die to form a linear form across the system. The resulting shape, which is commonly referred to as a rod but isn't always cylindrical, is then cooled before being chopped into various lengths depending on the programme. Extrusion moulding (also known as plasticisation extrusion) is a process in which a stack of powders or a green frame in a die is forced out to take on the shape of an actual frame or other end product under strain. Extrusion is one of the most widely used methods for producing fluoropolymer components. Extrusion, unlike injection moulding, usually produces a semi-finished or intermediate product that requires similar processes to reach a final product.

Injection Moulding

Injection moulding is a fun approach to mass-producing small, complex polymer components in large quantities. Injection moulding is a method of creating items by injecting fabric directly into a mould (shown in figure 03 b). Injection moulding can be done with a variety of materials, including metals, glassware, elastomers, confections, and, most commonly, thermoplastic and thermosetting polymers. The component's substance is put into a heated barrel, blended, cooled, and pressed into a mould cavity, where the cavity's configuration hardens. Molds shape the preferred component of the metal, usually metallic or aluminum, and are precision machined by both a mildew maker (and toolmaker) completed after a product has been designed, usually with the help of a business clothier or an engineer. Injection moulding is widely utilized to create a wide range of components, from minor components to whole motor frame panels. The material utilized for the component, the intended size and features of the part, the mildew cloth, and all houses of the

moulding device must all be taken into mind while designing injection moulded elements. This extension of design and possibilities aids injection moulding's versatility. At our Ogden, Utah location, Professional Plastics has two injection moulding machines. Through our clients, we also market plastic pellets for injection moulding. We also offer high-temperature materials utilised as thermal insulator nozzles in warm runners used in injection moulding machines as an expert in high-overall performance materials [8].

Advantages of Green Composites

- Lower high priced.
- Decrease weight.
- Better flexibility.
- Renewable useful resource.
- Sound insulation. • Thermal recycling is possible where glass poses troubles.
- Friendly processing and no pores inflammation.

Disadvantages of green composites

- Lower electricity homes (especially impact energy).
- Exact moisture absorption causing swelling of fibres.
- Lower durability.
- Terrible fire resistance and irregular fibre lengths are the native aspects. But recent fibre treatments have progressed these properties.

VII. CONCLUSION

After their lives are done, inexperienced composites can readily be composted, completing nature's carbon cycle. Green composites can be used to supplement and eventually replace petroleum-based composite materials in a variety of applications, providing additional agricultural, environmental, production, and customer benefits. Green composites made from plant-derived fibres (natural/bio-fibres) and crop-derived polymers are the new substances of the twenty-first century, and they could have enormous implications not only for the developing environment but also for the physical world. However, it can also be used as a deterrent to the unpredictability of petroleum delivery. Despite a few drawbacks, green composites have the potential to be the material of the future.
